ABSTRACT

Planorbid snails of the genus Biomphalaria are major intermediate hosts for the digenetic trematode parasite Schistosoma mansoni. Evidence suggests that levels of the neurotransmitter dopamine (DA) are reduced during the course of S. mansoni multiplication and transformation within the snail. This investigation used immunohistochemical methods to localize tyrosine hydroxylase (TH), the rate-limiting enzyme in the biosynthesis of catecholamines, in the nervous system of Biomphalaria. The two species examined, Biomphalaria glabrata and Biomphalaria alexandrina, are the major intermediate hosts for S. mansoni in sub-Saharan Africa, where more than 90% of global cases of human intestinal schistosomiasis occur. TH-like immunoreactive (THli) neurons were distributed throughout the central nervous system (CNS) and labeled fibers were present in all commissures, connectives, and nerves. Some asymmetries were observed, including a large distinctive neuron (LPeD1) in the pedal ganglion described previously in several pulmonates. The majority of TH-like immunoreactive neurons were detected in the peripheral nervous system (PNS), especially in lip and foot regions of the anterior integument. Independent observations supporting the dopaminergic phenotype of THli neurons included 1) block of LPeD1 synaptic signaling by the D2/3 antagonist sulpiride, and 2) the similar localization of aqueous aldehyde (FaGlu)-induced fluorescence. The distribution of THli neurons indicates that, as in other gastropods, dopamine functions as a sensory neurotransmitter and in the regulation of feeding and reproductive behaviors in Biomphalaria. It is hypothesized that infection could stimulate transmitter release from dopaminergic sensory neurons and that dopaminergic signaling could contribute to modifications of both host and parasite behavior. J. Comp. Neurol. 000:000–000, 2014.

INDEXING TERMS: Schistosoma mansoni; dopamine; pulmonate mollusk; pond snail; trematode

The parasitic disease schistosomiasis (snail fever) is estimated to impact 77 developing countries, where its socioeconomic toll is second only to malaria (Hotez, 2008; King, 2010; World Health Organization Media Centre, 2012). The trematode species Schistosoma mansoni that causes the most widespread form of intestinal schistosomiasis utilizes the planorbid snail Biomphalaria as its major intermediate host (Rollinson and Chappell, 2002; Bayne, 2009; Toledo and Fried, 2012). Published online Month 00, 2014 in Wiley Online Library (wileyonlinelibrary.com)
Biomphalaria glabrata and Biomphalaria alexandrina are the principal intermediate hosts for S. mansoni in sub-Saharan Africa, where ~90% of the global cases occur. Within the gastropod host, schistosome larvae undergo multiplication and transformation into cercariae that are capable of infecting humans.

Survival and propagation of trematode larvae within the snail both depend on complex bidirectional signaling between host and parasite (de Jong-Brink et al., 2001; Yoshino et al., 2001). Specific neurotransmitters that are shared by both schistosomes and gastropods, such as the biogenic amine dopamine (DA; 3,4-dihydroxyphenethylamine), are leading candidates for host–parasite communication, as both species possess the requisite synthetic enzymes, receptors, and uptake mechanisms necessary to achieve such signaling (Hamdan and Ribeiro, 1998; Taman and Ribeiro, 2009; Larsen et al., 2011).

Dopamine (DA) is a major neurotransmitter in the gastropod central nervous system (CNS) where it can produce both excitatory and inhibitory synaptic actions (Sweeney, 1963; Carpenter et al., 1971; Osborne and Cottrell, 1971; Ascher, 1972; Berry and Cottrell, 1973; McCaman et al., 1973). The presence of DA in B. glabrata was originally examined using spectrofluorometric measurements and its localization within the nervous system was demonstrated with histochemical fluorescence microscopy (Chiang et al., 1974). Significant reductions in DA content were measured in the Biomphalaria CNS during the course of S. mansoni infection (Manger et al., 1996). Recently, a DA transporter (SmDAT) was shown to be expressed at high levels in the parasitic stages of S. mansoni and it was proposed that the larval trematode could reduce its metabolic costs by scavenging DA from its host (Larsen et al., 2011). To date, however, potential neural sources of DA in Biomphalaria and the stimuli that could promote its release and availability to parasitoids have not been identified.

Histological findings indicate that DA also participates in sensory signaling by the peripheral nervous system (PNS) of gastropods (Osborne and Cottrell, 1971; Croll, 2001; Faller et al., 2008). While the modality of peripheral dopaminergic neurons remains uncertain, they are generally associated with cephalic sensory organs (CSOs) that mediate contact chemoreception and mechanoreception (Salimova et al., 1987; Croll et al., 2003; Wyeth and Croll, 2011). Peripheral dopaminergic neurons project to the CNS where their synaptic actions can influence the expression of behavior (Nargeot et al., 1999; Martinez-Rubio et al., 2009; Wyeth and Croll, 2011; Bédécarrats et al., 2013).

In addition to mediating rapid synaptic signaling, dopamine exerts widespread modulatory actions that can regulate entire neural circuits in the gastropod CNS (Wieland and Gelperin, 1983; Trimble and Barker, 1984; Kyriakides and McCrohan, 1989; Kabotyanski et al., 2000). Such modulation has been intensively studied in the central networks that control feeding, where specific dopaminergic neurons exert broad and coordinated influence over the central pattern generator (CPG) networks that control consummatory actions (Rosen et al., 1991; Teyke et al., 1993; Quinlan et al., 1997; Kabotyanski et al., 1998; Narusuye and Nagahama, 2002). The ability of these interneurons to implement qualitative and quantitative specification of feeding motor programs is attributable to their capacity to reconfigure multifunctional CPG networks (Kupfermann and Weiss, 2001; Murphy, 2001; Cropper et al., 2004). It has been proposed that such features of motor system control can provide opportunities for parasites to alter host behavior (see de Jong-Brink et al., 1999; Katz and Edwards, 1999; Adamo, 2002, 2005).

In this study, immunohistochemical methods were used to localize tyrosine hydroxylase (TH), the rate-limiting enzyme in catecholamine biosynthesis (see Osborne et al., 1975, 1976; Osborne, 1977), in the CNS and cephalopedal sensory organs of B. glabrata and B. alexandrina. Emphasis was placed on identification of catecholaminergic neurons that could serve as 1) sources of host-derived DA in the developmental and reproductive program of S. mansoni, and 2) potential targets for parasite-induced modification of snail behavior. Preliminary reports of these observations were presented in abstract form (Delgado et al., 2010; Vallejo et al., 2011).

**MATERIALS AND METHODS**

**Specimens, dissections, and nomenclature**

Experiments were conducted on B. glabrata that were reared in the laboratory in Puerto Rico and B. alexandrina that were collected from watercourses in Giza governorate, Egypt. The latter snails were held for 6 weeks in the Medical Malacology Laboratory, Theodor Bilharz Research Institute, Egypt, and examined on a weekly basis for natural infections before being shipped to Nova Scotia. All snails in the laboratory colonies were housed in glass or plastic aquaria at room temperature (21–25°C) and fed carrots or lettuce ad libitum. Tanks contained distilled water with Instant Ocean (Kingman AZ) added (1 g per gallon) to approximate pond water and crushed oyster shells or blackboard chalk as calcium supplements. Snails dissected at 6–10 mm shell diameter were considered sexually mature, as evidenced by their capacity to lay eggs. Protocols conducted on B. glabrata were approved by the
Institutional Animal Care and Use Committee (IACUC) of the University of Puerto Rico Medical Sciences Campus (Protocol #3220110). Protocols conducted on *B. alexandrina* were approved by the Animal Care Committee of Dalhousie University (Protocol #I13-06).

General features of the *Biomphalaria* nervous system have been reported previously (Lever et al., 1965; Chiang et al., 1972, 1974; Delgado et al., 2012). In the present study, a "head-brain" preparation was developed to facilitate visualizing relations between central and peripheral cephalic structures (Fig. 1). In this dissection, the body walls were reflected and pinned laterally following a longitudinal incision of the dorsal midline integument. An effort was made to maintain the innervation of the foot, lips, and tentacles as close as possible to its natural conformation. In most preparations, the reproductive and digestive systems were removed and the buccal ganglion was freed from the buccal mass by severing its peripheral nerves.

In preparations of the isolated nervous system and in nerve backfill experiments (below), two manipulations were implemented to obtain a planar configuration of the circumesophageal ring ganglia (see Delgado et al., 2012). For experiments in which the cerebral hemiganglia remained paired, the pedal commissure was severed and the pedal ganglia were rotated laterally (Figs. 2–5). In other experiments (Figs. 7 and 8) the cerebral commissure was severed and the cerebral hemiganglia were reflected to expose the dorsal surface of the paired pedal ganglia. These midline sections were performed following the backfill procedure to preserve visualization of contralateral neurons labeled via commissural projections.

Nerve designations followed previous reports (Pan, 1958; Lever et al., 1965; Chiang et al., 1972, 1974). The "foot-brain" preparation confirmed earlier descriptions of CSO innervation, i.e., the nerve projecting to the superior lip (superior lip n.) originates medial to the nerve innervating the median lip (median lip n.) in the anterolateral cerebral ganglion (Lever et al., 1965). The two nerves cross in the periphery, taking tortuous routes to their targets (Fig. 1B). The nomenclature adopted for the pedal nerves followed Chiang et al. (1972) with the designations of anterior pedal nerve, central pedal nerve, and posterior pedal nerve corresponding respectively to nerves 10, 11, 12 used previously (Delgado et al., 2012; see Kemenes et al., 1989). Neuron cluster labels followed common usage in the intensively studied pulmonate, *Lymnaea stagnalis* (Slade et al., 1981; Benjamin and Winlow, 1981; Kemenes et al., 1989; Croll and Chiasson, 1990). As *Lymnaea* is a dextral species, the nomenclature used previously for the sinistral *Helisoma trivolvis* (Syed et al., 1993; Kiehn et al., 2001) was adopted when applicable (see Delgado et al., 2012).

**Wholemount immunohistochemistry**

Specimens were dissected in snail saline with the following composition (in mmol l \(^{-1}\)): NaCl 51.3, KCl 1.7, MgCl\(_2\) 1.5, CaCl\(_2\) 4.1, HEPES 5, pH 7.8. Tissues were

![Figure 1.](image-url)
fixed for 30 minutes in cold methanol 99%, glacial acetic acid 1%. Following fixation, tissues were washed (5 × 20 min) in 80 mM phosphate buffer containing 2% Triton X-100 and 0.1% sodium azide (solution referred to below as PTA).

Following preincubation with normal goat serum (0.8% in PTA, 3–5 hours, room temperature), tissues were immersed (1–7 days, 4°C) in a mouse monoclonal antibody (ImmunoStar, Stillwater MN; Product No. 22941; JCN Antibody Data Base entries 5523–5529; NIH Neuroscience Information Framework Antibody Registry Identification Number: AB_572268) generated against rat TH (lot LNC1 purified from rat pheochromocytoma [PC12] cells). Primary antibody concentrations ranged from 1:100 to 1:300 (see Díaz-Ríos et al., 2002; Martínez-Rubio et al., 2009). This antibody possesses wide species cross-reactivity, which is proposed to reflect its recognition of a highly conserved epitope in the mid-portion of the TH molecule (ImmunoStar Specification Sheet 22914). It specifically labels neurons that are stained using several independent techniques for catecholamines, including the glyoxylic acid (Rathouz and Kirk, 1988; Elekes et al., 1991; Kabotyanski et al., 1998) and the formaldehyde (Fa)/glutaraldehyde (Glu) histofluorescence techniques (Quinlan et al., 1997; Croll, 2001; Díaz-Ríos et al., 2002). Additional biochemical and pharmacological studies indicate that DA is the major catecholamine neurotransmitter in gastropods (Carpenter et al., 1971; McCaman et al., 1973, 1979; Osborne et al., 1975; Trimble et al., 1984), and that DA mediates synaptic signaling by neurons labeled with this antibody (Teyke et al., 1993; Magoski et al., 1995; Quinlan et al., 1997; Díaz-Ríos and Miller, 2005). Collectively, these observations support the utility of this antibody for labeling gastropod neurons with a dopaminergic phenotype.

Figure 2. TH-like immunoreactivity on the dorsal aspect of the cerebral ganglion. A: Dorsal surface of *B. glabrata* cerebral ganglion. The superior lip nerve (SL n.), medial lip nerve (ML n.), and the tentacular nerve (T n.) are densely filled with immunoreactive fibers. Several neurons are located near the origin of each T n. (dashed box, B). Diffuse staining is present in the medial dorsal bodies (mdb) adjacent to the cerebral commissure and the lateral dorsal bodies (ldb) bordering the posterior margin of each hemiganglion. Scale bar = 100 μm. B: Region enclosed by dashed box in panel A; not from the same preparation. Neurons with prominent axons (arrow) near the origin of the tentacular nerve of *B. glabrata*. An aggregate of 10–12 small (10–20 μm) THli neurons (arrowhead) is also observed anteromedial to the T n. origin. Scale bar = 50 μm. C: Neurons with prominent axons (arrow) near the origin of the T n. in *B. alexandrina*. Scale bar = 50 μm. D: Densely packed elongated profiles in the dorsal body of *B. alexandrina*. A prominent unstained nucleus is present in each cell. Scale bar = 20 μm. E: The lateral dorsal body cortex of *B. glabrata* is filled with small perikarya of varied sizes (5–10 μm) and shapes. Scale bar = 30 μm.
Following repeated PTA washes (5 times, at least 30 min each, room temperature), ganglia were incubated in secondary antibodies conjugated to fluorescent markers (Alexa 488 goat antimouse IgG [H+L] conjugate or Alexa 546 goat antimouse IgG [H+L]; Molecular Probes, Eugene, OR). Secondary antibody dilutions ranged from 1:1,000 to 1:600 and incubation times ranged from 2 to 10 days. Control experiments in which either the primary or secondary antibodies were omitted resulted in the elimination of labeling.

Processed tissues were initially examined and photographed on a Nikon Eclipse or Leica DM 4000B fluorescence microscope. Imaging of favorable preparations was performed on a Zeiss Laser Scanning Confocal Microscope (Pascal LSCM) or on a Zeiss LSM 510 (META). Stacks of optical sections (0.2–1.5 μm) were collected to generate maximum intensity projections. Confocal images were captured in the Zeiss LSM 5 Image Browser (v. 3.1.0.11) or Zen programs of the META. Stacks, z-series, overlays, and calibrations were generated using ImageJ software (v. 1.43u, NIH public domain).

**Figure 3.** TH-like immunoreactivity on the ventral surface of the cerebral ganglion. **A:** A group of superficial neurons (dashed box, B,C) is located near the confluence of intensely stained fiber tracts converging from the major cerebral nerves and the cerebral commissure (C c.); *B. glabrata* shown. Additional immunoreactive cell groups are present near the cerebral commissure (dashed box, D) and at the anterolateral margin of ganglion near the origin of the medial lip nerve (dashed box, E,F). Scale bar = 50 μm. **B:** Neurons near the convergence of the cerebral nerves on the ventral surface of the left cerebral hemiganglion (*B. glabrata*, not the same preparation as A). The axons of the two most intensely stained cells were oriented in the lateral direction, away from the C c. (arrow). Scale bar = 20 μm. **C:** Neurons near the convergence of the cerebral nerves and the cerebral commissure of *B. alexandrina*. The axons of the two most intensely stained cells were oriented in the lateral direction (arrow). Scale bar = 20 μm. **D:** Cerebral commissure of *B. glabrata* (same preparation as A). A cluster of small neurons in the anteromedial region of the right hemiganglion gives rise to a thin fascicle of fibers projecting in the posterior direction (arrow). Scale bar = 20 μm. **E:** THII neurons in the anterolateral region of the *B. glabrata* cerebral ganglion (same preparation as A). A single neuron (arrow) is located lateral to the ML n. tract and a group of cells is positioned near the origin of the nerve (arrowhead). Scale bar = 20 μm. **F:** Anterolateral region of the ventral CG of *B. alexandrina*. The solitary neuron adjacent to the ML n. (arrow) projected one fiber toward the periphery and another centrally. As in *B. glabrata*, a cluster of smaller neurons was present near the base of the ML n. (arrowhead). Scale bar = 20 μm.
domain). Images were imported to CorelDraw 10 or Microsoft PowerPoint v. 14.0.0 files for addition of labels, adjustment of brightness/contrast, and organization of panels.

**Formaldehyde–glutaraldehyde histochemical staining**

The localization of catecholamines in the nervous system of *Biomphalaria* was substantiated with the FaGlu method of Furness et al. (1977), as modified by Croll and Chiasson (1990) for wholemount molluscan tissues. Briefly, dissected ganglia and peripheral tissues were fixed overnight at 4°C in a solution of 4% paraformaldehyde and 0.5% glutaraldehyde (Electron Microscopy Sciences, Fort Washington, PA, 16320) in 0.1 M phosphate-buffered saline (PBS) adjusted to pH 7.4. The tissues were then rinsed twice in 0.1 M PBS, air-dried overnight (Hauser and Koopowitz, 1987), and mounted between glass coverslips in a 3:1 solution of glycerol to 0.1 M Tris buffer (pH 8.0) with the addition of 2% n-propyl galactate for imaging using the Leica DM 4000B microscope. Blue-green fluorescence under UV illumination was indicative of catecholamines, as reported in other gastropods (Quinlan et al., 1997; Croll, 2001; Díaz-Ríos et al., 2002). Control tissues fixed without glutaraldehyde exhibited no corresponding fluorescence.

**Nerve backfills**

Dissection protocols were performed as described above. Dissected ganglia were positioned with minuten pins near a small petroleum jelly (Vaseline) enclosure (3–5 mm diameter) on the surface of a Sylgard-lined Petri dish. The nerve of interest was cut and its end was drawn into the Vaseline-lined pool. The saline was
The nerve was then extracted from the pool and the ganglia were repinned and washed 3–5 times with saline. Following fixation in 4% paraformaldehyde (see Díaz-Ríos et al., 2002), tissues were transferred to microcentrifuge tubes, washed 5 times (30 min each) with PTA solution, and incubated in Alexa Avidin 488 (Molecular Probes) diluted 1:1,000 to 1:2,000 in PTA (24–48 hours, room temperature). The preparations were assessed daily (1–5 days) until the quality of the backfill staining was determined to be sufficient for advancing to immunohistochemical processing.

**Electrophysiology**

Ganglia were pinned to a Sylgard-lined chamber and exposed to protease (Sigma Type XIV, 1.2 mg/ml, 15–20 min) dissolved snail saline to facilitate electrode penetration through the external sheath. Microelectrode tips were filled with 4% Neurobiotin (Vector Laboratories, Burlingame CA) dissolved in 0.5 M KCl, and 50 mM Tris (pH 7.6). The shaft of the pipette contained 2 M KCl prior to superfusion.

Figure 5. TH-like immunoreactivity in the buccal ganglion. **A:** Asymmetric distribution of immunoreactive cell bodies on the caudal surface of the buccal ganglion of *B. glabrata*. Two lateral THI neurons are present in each buccal hemiganglion and an unpaired neuron (arrow) is located in the right buccal hemiganglion near the buccal commissure. Additional clusters of small (5–10 μm) weakly stained neurons are present in the ventromedial and dorsomedial region of each hemiganglion. Prominent THI fibers course through the buccal commissure (B c.) and in the buccal nerves. Two to three fibers were observed in each cerebral-buccal connective (C-b c.). Scale bar = 50 μm. **B:** Rostral surface of *B. glabrata* buccal ganglion. A single strongly immunoreactive cell (arrows) is located in each hemiganglion near the buccal commissure. Smaller cells with weaker staining are distributed through the medial regions of both hemiganglia. Scale bar = 50 μm. **C:** Higher magnification of the two lateral caudal THI neurons (left buccal ganglion of *B. glabrata*, dashed rectangle of panel A). Both neurons project fibers toward the central commissural bundle (arrows). Scale bar = 40 μm. **D:** Lateral region of left buccal ganglion of *B. alexandrina*; dorsal surface, approximately same area shown for *B. glabrata* in C. Lateral THI neurons give rise to processes projecting toward the central commissural bundle (arrows). Scale bar = 40 μm.

withdrawn from the pool and replaced with a saturated solution (1.4 mg / 50 μl dH2O) of biocytin (Sigma-Aldrich, St. Louis MO). The enclosure was sealed with Vaseline and the preparation was incubated overnight at room temperature to allow migration of the biocytin.
Neuron labeling
Depolarizing current pulses (1–2 nA; 0.5 sec; 1 Hz; 30–60 min) were used to eject the Neurobiotin from the pipette tips. Preparations were incubated overnight (4°C) to allow injected material to diffuse from the cell body to small and distant processes. Ganglia were then repinned and fixed as described above. The fixed ganglia were transferred to microcentrifuge tubes and washed five times (30 min each) with PTA solution. They were then incubated in Alexa Streptavidin 546 (Molecular Probes) diluted (1:800 to 1:3,000) in PTA (24–48 hours, room temperature). Tissues were washed five times with PTA and viewed on the Nikon Eclipse TE200 fluorescence microscope prior to immunohistochemistry processing.

RESULTS
THli neurons were widely distributed throughout the CNS and immunoreactive fibers were present in all major connectives and commissures of both B. glabrata and B. alexandrina. While the patterns of THli were highly similar between the two species, some differences were observed in the positions and occurrence of specific cells and clusters. In addition to the central THli neurons, thousands of subepithelial sensory neurons were present in the body wall of both species. The patterns of FaGlu staining in both the CNS and PNS were consistent with the localization of THli, supporting the hypothesis that these cells contain catecholamines.

Cerebral ganglion
THli neurons were present on the dorsal and ventral aspects of the cerebral ganglion (Figs. 2–4). Most of the THli neurons visible from the dorsal surface of the cerebral ganglia were proximate to the base of the tentacular nerve (T n., Fig. 2A–C). Four to six moderately sized (15–20 μm) cells positioned near each tentacular nerve gave rise to processes oriented in the medial direction toward the origin of the tentacular nerve fiber tract (e.g., Fig. 2A–C). A compact cluster of 10–12 smaller (10–15 μm) neurons was positioned anteromedial to the tentacular nerve, ~50 μm below the dorsal surface (Fig. 2A,B). The cells comprising this cluster were oriented in a posterolateral direction and their axons converged to project in the direction of the tentacular nerve.

TH-like staining was present in two bilateral structures corresponding to the mediodorsal bodies (MDB) and laterodorsal bodies (LDB) described initially in Lymnaea stagnalis by Joosse (1964; Fig. 2A,D,E). The MDB (Fig. 2A,D) adhered to the cerebral commissure and the LDB (Fig. 2A,E) protruded from the posterior edge of each hemiganglion. In both dorsal bodies, staining was observed in small (4–6 μm diameter) densely packed cells with large prominent nuclei (Fig. 2D,E).

The majority of THli neurons on the ventral surface of the cerebral ganglion were located near the confluence of the lip nerves and the cerebral commissure (Fig. 3A–C). These neurons exhibited a range of sizes (10–20 μm), shapes, and staining intensities (Fig. 3B,C). Two brightly stained cells were distinguished on the surface of the cerebral ganglia in both B. glabrata and B. alexandrina. Prominent axons projected from these cells in the lateral direction (Fig. 3B,C, arrows). In both species, a group of five to six intensely stained somata was located 10–20 μm below the surface (Fig. 3B,C, arrowheads).

The cerebral commissure (Fig. 3A, C c.) contained numerous immunoreactive fibers, some of which formed a compact fascicle (Fig. 3D). The only unpaired THli neurons detected in the cerebral ganglia formed a cluster of 6–8 small (soma diameter 10–15 μm) cells near the ventral surface of the right cerebral hemiganglion (Fig. 3D). The axons of these cells converged and projected toward the posterior cerebral commissure (Fig. 3D, arrow). The remaining ventral THli neurons were present in the lateral region of the cerebral ganglia near the origin of the medial lip nerve and cerebral-buccal connective (Fig. 3E,F). These cells exhibited a range of sizes (10–30 μm) and staining intensities. In some preparations, fibers from this cluster could be seen to enter the cerebral-buccal connective (see Fig. 4). A prominent bipolar neuron protruded from the lateral edge of the medial lip nerve, giving rise to axons that joined this nerve in both the centripetal and centrifugal directions (Fig. 3E,F).

Major THli fiber projections were present in the tentacular nerve (Fig. 2A) and in the superior and medial lip nerves (Fig. 4A). In preparations where the nervous system remained connected to the lips and tentacles (see Fig. 1A), the lip nerves projected to a population of distal THli neurons (Fig. 4A,B). The peripheral THli cell bodies (6–8 μm in diameter) lined the lips, projecting apical processes (20–30 μm) through the epithelium toward the surface (Fig. 4B). They did not extend beyond the epithelial surface, where they terminated in a bulbous swelling (Fig. 4C). Longer proximal processes converged in branches of the lip nerves projecting toward the CNS. When the lips were viewed from the exterior surface, the distal processes of the THli cells were observed to fully penetrate the epithelium of the superior and medial lip regions (Fig. 4D).

Buccal ganglion
THli neurons were present on the caudal and rostral surfaces of the buccal ganglion (Fig. 5). Caudal cells
included a pair of lateral neurons positioned near the confluence of the esophageal nerve and the cerebral-buccal connective of each hemiganglion (Fig. 5A,C,D). In both *B. glabrata* and *B. alexandrina* these neurons gave rise to axons projecting toward the buccal commissure (Fig. 5C,D, arrows). In addition to these bilateral neurons, an unpaired immunoreactive neuron was present near the buccal commissure on the caudal surface of the right hemiganglion (Fig. 5A, arrow). Smaller (5–10 μm) neurons exhibiting weaker immunoreactivity were distributed throughout the buccal ganglion. On the rostral surface, a pair of moderately sized (15–20 μm) strongly staining cells flanked the buccal commissure (Fig. 5B, arrows) and additional small cells were observed. Prominent TH-like fiber tracts were present in the buccal commissure, the esophageal trunk, and the cerebral-buccal connective.

The presence of TH-like fibers in the cerebral-buccal connective (Fig. 5A) prompted experiments using double-labeling (biocytin backfills combined with TH immunohistochemistry) to localize catecholaminergic projection neurons in the cerebral ganglia that could participate in the regulation of feeding motor patterns (see Rosen et al., 1991, Narusuye and Nagahama, 2002). Most of the neurons labeled with cerebral-buccal connective backfills were located in the anterior quadrant of the ipsilateral cerebral hemiganglion (Fig. 6A; see also Delgado et al., 2012). These included the...
large C1 neuron (Fig. 6A), shown previously to contain serotonin-like immunoreactivity (Delgado et al., 2012). Subsequent processing for THli demonstrated double labeling in a small (15–20 μm) neuron near the origin of the cerebral-buccal connective lateral to the medial lip nerve (Fig. 6B–F). No additional double-labeled neurons were detected.

Pedal ganglion

The most distinctive TH-like immunoreactive neuron in the CNS was located on the posterior margin of the left pedal ganglion (Fig. 7A–D). The soma of this neuron ranged from 40–60 μm in diameter. It was positioned on the dorsal surface bordering the medial edge of the statocyst, but it was also readily viewed from the ventral aspect due to its large size, peripheral position, and intense staining (Fig. 7B). The initial segment of the major axon appeared to be lined by a lattice of fine immunoreactive fibers (Fig. 7C, arrow). The principal axon coursed in the anterolateral direction, giving rise to several finer branches prior to turning toward the pleural ganglion (Fig. 7C,D). All of these characteristics support the homology of this neuron with the LPeD1 cell of Helisoma trivolvis (Syed et al., 1993), the giant dopamine cell of Planorbis corneus (Pentreath et al., 1974), and the giant dopaminergic RPeD1 neuron of Lymnaea (Cottrell, 1977; Cottrell et al., 1979; McCaman et al., 1979; Slade et al., 1981; see Discussion).

Two additional THli neurons were present in the central region of the dorsal surface of each pedal ganglion (Fig. 7A, arrows). One of these cells was typically larger, more superficial, and more strongly stained than the other. The fibers from these neurons projected toward the pleural ganglion. Two clusters of smaller (10–15 μm) THli neurons were present in the anterolateral quadrant of each pedal ganglion, between the origins of the anterior pedal nerve and central pedal nerve (Fig. 7B,E). These clusters were composed of 6–8 elongated neurons and were more readily viewed from the ventral aspect of the ganglion (Fig. 7B,E). Finally, a group of 8–10 small (10–15 μm) neurons present on the medial dorsal surface of the pedal ganglion in B. alexandrina (Fig. 7F) was not observed in B. glabrata.

The central region of each pedal ganglion contained a dense fiber network and the three pedal nerves projecting to the foot were densely filled with immunoreactive fibers (Fig. 7A,B). When these nerves were followed to their peripheral terminations, small THli bipolar neurons were observed lining the pedal epithelium (Fig. 7G). These neurons had the same size (6–8 μm diameter) and anatomical characteristics as described above for the THli neurons in the lips (cf. Fig. 4).

The large size and accessibility of LPeD1 prompted electrophysiological and pharmacological experiments to further test the role of dopamine as a neurotransmitter in neurons labeled in this study. The RPeD1 neuron of Lymnaea and LPeD1 of Helisoma participate in the central pattern generator (CPG) circuit for aerial respiration (Syed et al., 1990, 1993; Syed and Winlow, 1991; Moroz and Winlow, 1992). In normal saline, the LPeD1 neuron of B. glabrata exhibited repetitive burst activity (Fig. 8A, lower record), suggesting that it also functions in the respiratory CPG. In agreement with observations in the other species, numerous motor neurons in the posteromedia l quadrant of the visceral ganglion (I cluster) were observed to fire out of phase with LPeD1 (Fig. 8A, upper record). When the saline was replaced with a high-Ca²⁺/high-Mg²⁺ solution to attenuate polysynaptic activity, inhibitory postsynaptic potentials (IPSPs) were observed in the visceral neuron following each LPeD1 impulse (Fig. 8B). These IPSPs occurred with a brief and constant latency following each LPeD1 spike, indicative of direct chemical synaptic transmission. When LPeD1 was fired with progressively larger depolarizing intracellular current pulses, the IPSPs became fused and exhibited summation (Fig. 8C, left panel). Addition of sulpiride (100 μM), a selective D2/D3 antagonist of dopaminergic signaling in gastropods (Magoski et al., 1995; Quinlan et al., 1997; Diaz-Rios and Miller, 2005), blocked the IPSPs elicited by LPeD1 in a reversible fashion (Fig. 8C, middle panel). Following each experiment with sulpiride (n = 4), the pre- and postsynaptic neurons were filled with neurobiotin and processed for TH-like immunoreactivity (Fig. 8D–F). These observations support the role of dopamine as a neurotransmitter in the neurons labeled in this study.

Pleural, parietal, and visceral ganglia

In B. glabrata, a single immunoreactive neuron was located at the posterolateral edge of the ventral surface of the left pleural ganglion (Fig. 7B, arrow). This neuron was not detected in B. alexandrina, where the left pleural ganglion was devoid of TH-like-immunoreactive cell bodies. In both species, the left pleural ganglion and left parietal ganglion were traversed by several THli fibers, including the large axon of the LPeD1 neuron en route to the left parietal ganglion (Fig. 9A,B; see also Fig. 7B,F). One branch of the LPeD1 neuron entered the external left parietal nerve (Fig. 9A, arrow, B) and continued toward the periphery following its anastomosis with the anal nerve posterior to the visceral ganglion (Fig. 9A,E; see Lever et al., 1965). Additional branches of LPeD1 projected to the internal left parietal nerve (Fig. 9A,B) and to the visceral ganglion (Fig. 9B).
While three small neurons were present on the dorsolateral surface of the right parietal ganglion (R Pa g.) of *B. alexandrina* (not shown), none were detected in the R Pa g. of *B. glabrata*. In both species, two cell bodies were located in the central region of the left parietal ganglion near the
bifurcation of the LPeD1 fiber (Fig. 9A,C). The more superficial cell of the pair was typically larger (20–30 µm) and more intensively stained than the deeper cell (15–20 µm). Projections from both left parietal ganglion cells were oriented toward the visceral ganglion.

Figure 8. Pharmacological support for the dopaminergic phenotype of labeled neurons. A: Intracellular recording from LPeD1 (lower trace) of B. glabrata; isolated CNS in normal saline solution. The recording exhibits alternating phases of activity and quiescence. A putative cardiorespiratory motor neuron in the visceral ganglion (VJ Mn, upper trace) was observed to burst out of phase with LPeD1. Calibration bars: 5 sec, 20 mV. B: Changing the bathing medium to a raised divalent saline solution (Hi-Di) eliminated polysynaptic signaling, enabling resolution of direct one-to-one inhibitory postsynaptic potential (IPSPs, upper record). Each IPSP occurred with a brief and constant latency following each LPeD1 impulse (lower record). Calibration bars = 1 sec; 5 mV, upper record; 20 mV, lower record. C: Pharmacological evidence for direct dopaminergic signaling from LPeD1 to VJ Mn. Control: Depolarizing current pulses were passed into LPeD1 producing sequentially greater number of impulses (lower record). The IPSPs produced in the VJ Mn became progressively larger as more impulses were stimulated. When the dopaminergic (D2) antagonist sulpiride was added to the solution (100 µM), the IPSPs were blocked. They returned following 15-minute wash (right panel). Calibration bars = 0.5 sec, 20 mV, 20 mV. D–F: Morphological confirmation of LPeD1 and VJ Mn identity. D: Neurobiotin was injected into LPeD1, a second neighboring cell in the pedal ganglion, and the VJ Mn. The three injected neurons were visualized with Avidin 546 (false-color magenta). The axon of LPeD1 can be seen descending through the left pleural ganglion (arrow), while the neighboring cell projects to the contralateral pedal ganglion (arrowhead). E: When the preparation was processed for TH-like immunoreactivity and viewed with Avidin 488 (green), only the LPeD1 neuron and its descending axon (arrow) were labeled. F: When the fill (D) and immunohistochemical (E) panels are overlaid, only the LPeD1 neuron and its descending axon (arrow) appear white (colocalization). The other injected cells, VJ Mn and the neighboring pedal neuron (arrowhead), appear magenta. Scale bar = 50 µm, applies to D–F.
Two THli cell bodies were also observed near the ventral surface of the visceral ganglion, adjacent to the LPeD1 axon (Fig. 9A,D). The more superficial neuron of the pair was again larger (20–30 \( \mu \text{m} \)) and more intensely stained than the deeper cell (15–20 \( \mu \text{m} \)). Multiple fibers projected from both somata (Fig. 9D, arrows). Axons from the larger cell projected to the intestinal and anal nerves (Fig. 7E).

**Peripheral neurons**

As described above, the tentacular, lip, and pedal nerves contained large numbers of THli fibers that projected from sensory neurons in the body wall. THli axons were similarly present in all peripheral nerves innervating the integument. A few immunoreactive cell bodies were embedded within peripheral nerves, such as the esophageal trunk (not shown) and the external left parietal nerve near its juncture with the anal nerve (Fig. 9A,E). However, the vast majority of THli axons in peripheral nerves originated from sensory neurons lining the body wall in all regions of skin examined. The THli peripheral cells were especially dense on the ventral lateral surface of the mantle, ventral surface and along the entire margin of

**Figure 9.** TH-like immunoreactivity in the left parietal and visceral ganglia. A: Ventral surface of the left parietal ganglion (L Pa g.) and the visceral ganglion (V g.) of *B. glabrata*. The LPeD1 axon (arrowhead) descends to the central region of the L Pa g., where it gives rise to branches in the external left parietal nerve (E L Pa n.) and the internal left parietal nerve (I L Pa n.). Following fusion of the E L Pa n. with the anal nerve (A n.), the LPeD1 axon continued toward the periphery. Dashed rectangles indicate regions shown at higher magnification in panels C–E. Scale bar = 50 \( \mu \text{m} \). B: Dorsal view of left parietal ganglion (*B. glabrata*) shows branch of LPeD1 projecting to the visceral ganglion (V g.). Scale bar = 50 \( \mu \text{m} \). C: Two cell bodies in the central neuropil of the left parietal ganglion (*B. glabrata*). One of these cells is more superficial and larger (30–40 \( \mu \text{m} \)) than the other (20–30 \( \mu \text{m} \)), which is embedded in the central neuropil (arrow). Scale bar = 30 \( \mu \text{m} \). D: Two immunoreactive cell bodies in the central neuropil of the visceral ganglion (*B. alexandrina*). Multiple fibers project from the somata of both cells (arrows). Scale bar = 30 \( \mu \text{m} \). E: Anastomosis of the E L Pa n. and the A n. posterior to the visceral ganglion (*B. glabrata*). A single elongated neuron is embedded within the E L Pa n. Scale bar = 30 \( \mu \text{m} \).
the lip, and on the dorsal medial surface of the foot (Figs. 4B–D, 7G).

**FaGlu histochemistry**

FaGlu histochemistry was used as a second marker for catecholamines in the *Biomphalaria* nervous system. Neurons stained with FaGlu exhibited intense fluorescence that generally contrasted well with background, but resolution of detail was limited due to diffuse staining of fiber systems within the ganglia. The localization of FaGlu-induced blue-green fluorescence was in agreement with the distribution of the TH-like immunoreactivity. The vast majority of cells marked with FaGlu were located in the periphery where they lined the cephalic sensory organs and other regions of the integument (Fig. 10A). FaGlu-labeled peripheral sensory cells had an epithelial process, were bipolar, and were particularly dense along the edges of the lips and anterior foot, supporting their correspondence to the THli

---

**Figure 10.** FaGlu histofluorescence of catecholamines in the PNS and CNS of *B. alexandrina*. A: Peripheral sensory cells in the lips. B: Two large intensely stained neurons (arrows) were located near the lateral edge of each buccal hemiganglion and groups of small neurons flanked the buccal commissure (B c.). C: Dorsal surface of the left cerebral ganglion. Intensely stained neurons were positioned near the origin of the tentacular nerve (T n.). D: Cluster of neurons on the mediadorsal surface of the right cerebral ganglion. E: The large LPeD1 neuron viewed from the dorsal surface of the left pedal ganglion with its large axon turning toward the pleural ganglion (Pl g.). A cluster of neurons (arrow) is located near the origin of the anterior pedal nerve (A Pd n.). F: Labeled neurons (arrow) were located near the origin of the anterior pedal nerve on the dorsal surface of the right pedal ganglion. Scale bars = 50 μm, all panels.
peripheral neurons. Within the CNS, two prominent neurons were located near the lateral margin of each buccal hemiganglion (Fig. 10B), groups of stained neurons were present near the origin of the tentacular nerve (Fig. 10C,D), and the pattern of labeled neurons in the pedal ganglia was in agreement with THli (Fig. 10E,F). A notable inconsistency between the two methods was the absence of FaGlu staining in the medial and lateral dorsal bodies.

DISCUSSION

The localization of THli observed in the CNS of B. glabrata and B. alexandrina (summarized schematically in Fig. 11) is in overall agreement with prior reports in several pulmonates, including Helix pomatia (Dahl et al., 1966; Hernádi et al., 1989), Planorbis corneus (Marsden and Kerkut, 1970), Lymnaea stagnalis (Audesirk, 1985; Croll and Chiasson, 1990; Werkman et al., 1991; Elekes et al., 1991; Sakharov et al., 1996; Croll et al., 1999), and Helisoma duryi (Kiehn et al., 2001). A previous study also used fluorescence spectroscopy and histochemical fluorescence microscopy to demonstrate the presence of catecholamines in the CNS of B. glabrata (Chiang et al., 1974).

In early studies using glyoxylic acid histofluorescence techniques, intense staining of the neuropil regions rendered localization of central catecholaminergic neurons...
challenging (Marsden and Kerkut, 1970; Chiang et al., 1974; Audesirk, 1985; see Fig. 10 of this report). These limitations were reduced with the application of immunohistochemical approaches and serial sectioning of ganglia (Croll and Chiasson, 1990; Elekes et al., 1991; Werkman et al., 1991). In the present investigation, the combination of immunohistochemistry and optical sectioning of whole mount ganglia using confocal microscopy produced a localization of central catecholaminergic cell bodies that should facilitate electrophysiological and functional characterization of catecholaminergic neurons in *Biomphalaria*.

The FaGlu histochemical staining protocol provided independent support for the catecholaminergic phenotype of neurons labeled for TH. Some labeled neurons could use norepinephrine (NE) as a neurotransmitter as low levels of NE have been detected in pulmonate nervous systems, but studies consistently demonstrate that dopamine is the predominant catecholamine (Hernadi et al., 1993; Trimble et al., 1984; Quinlan et al., 1997), Limax and *Helisoma* have homologs in other gastropods, suggesting their conservation across this taxon. For instance, other pulmonate species have similar clusters of catecholaminergic cells distributed across the cerebral ganglia and near the origins of the pedal nerves (Croll, 1988; Croll et al., 1999). Moreover, the anatomical features and dopaminergic phenotype of the large pedal neuron in *Biomphalaria* are indicative of homology with the giant dopamine cell (GDC) of *Planorbis corneus* (Berry and Cottrell, 1973, 1975) and the left pedal dorsal 1 (LPeD1) neuron of *Helisoma trivolvis* (Syed et al., 1993; Harris and Cottrell, 1995). The location of this cell in *Biomphalaria* reflects the sinistrality of these species. In the dextral species *Lymnaea stagnalis*, where the central ganglia are organized as a mirror image of the sinistral CNS, the dopaminergic RPeD1 neuron exhibits all of the anatomical characteristics observed in this study (Cottrell, 1979; Benjamin and Winlow, 1981; Syed and Winlow, 1989). Maintaining consistency with the most common nomenclature in *Lymnaea* and *Helisoma*, we have adopted the designation of left pedal dorsal 1 (LPeD1) neuron for this cell in *Biomphalaria*.

The function of RPeD1 has been extensively studied in *Lymnaea*, where it acts as an influential interneuron in the central pattern generator circuit controlling aerial respiration (Winlow et al., 1981; Syed et al., 1990, 1992; Syed and Winlow, 1991). Our observations, in which LPeD1 was found to produce rhythmic burst activity in the isolated CNS and to produce direct inhibition of putative motor neurons in the visceral ganglion are consistent with such a role in *Biomphalaria*. Blockade of these IPSPs by sulpiride, a D2/3 antagonist that blocks inhibitory and excitatory dopaminergic synapses in gastropods, provides further support for the dopaminergic phenotype of TH-positive neurons labeled in this study (see Magoski et al., 1995; Quinlan et al., 1997; Due et al., 2004; Díaz-Ríos and Miller, 2005).

The distribution of THli neurons in the feeding system of *Biomphalaria* suggests additional homologies to cells identified previously in other gastropods. In *Aplysia* and *Helisoma*, influential dopaminergic interneurons are located in the buccal ganglion, within the multifunctional neural circuit that controls oral behaviors (Teyke et al., 1993; Quinlan et al., 1997; Kabotyanski et al., 1998). Murphy (2001) noted physiological and structural commonalities between specific buccal neurons of the pulmonate *Helisoma* and the opisthobranch *Aplysia* and advanced the hypothesis of a "universal gastropod tripartite buccal central pattern generator" (Murphy, 2001; see also Wentzell et al., 2009). Homology was proposed between dopaminergic neurons located near the lateral edge of the caudal surface of the ganglion (N1a in *Helisoma* and B65 in *Aplysia*) and between dopaminergic interneurons located near the buccal commissure (N1b of *Helisoma* and B20 of *Aplysia*). The configuration of buccal catecholaminergic neurons in *Biomphalaria* bears considerable similarity with other gastropods and should provide further opportunities to test the proposal of a universal gastropod CPG.

**Catecholamines and the control of behavior**

One aim of this study was to identify catecholaminergic neurons that could participate in interactions between *Biomphalaria* and trematode parasites. For instance, the presence of THli neurons projecting from the cerebral to the buccal ganglion supports a role for DA in the regulation of feeding. Modifications of feeding behavior in infected *Biomphalaria* have been reported and attributed to altered energy requirements for cercarial production versus egg production (see following text; Meuleman, 1972; Gilbertson, 1983). Application of exogenous DA evokes coordinated buccal motor patterns (BMPs) in several gastropods, including the pulmonates *Helisoma trivolvis* (Trimble and Barker, 1984; Trimble et al., 1984; Quinlan et al., 1997), *Limax*
maximus (Wieland and Gelperin, 1983; Wieland et al., 1987), and Lymnaea stagnalis (Kyriakides and McCrohan, 1989). In Aplysia californica, a bilateral pair of dopaminergic cerebral-buccal interneurons (CBIs), termed CBI-1, were shown to respond to tactile stimuli to the tentacles, lips, and buccal mass, and to evoke a BMP when fired repetitively (Rosen et al., 1991). A pair of dopaminergic cerebral neurons (CBM1) in Aplysia kurodai that are proposed to be homologous to CBI-1 of A. californica bias the feeding motor circuitry toward the rejection of nonpreferred foods (Narusuye and Nagahama, 2002). Together, the presence of THli neurons within the buccal circuit and others projecting from the cerebral ganglion support pivotal "intrinsic" and "extrinsic" regulatory roles for DA in the control of Biomphalaria feeding circuits (see Katz, 1995; Katz and Frost, 1996). This neural architecture affords opportunities for parasites to modify consummatory behavior by altering the activity of specific target neurons (see Katz and Edwards, 1999; Adamo, 2002; Lefèvre et al., 2009).

The presence of THli in the dorsal bodies suggests that DA could also be involved in the diminished egg laying, or "parasitic castration," observed in infected snails (de Jong-Brink et al., 1995, 2001). Surgical removal of the dorsal bodies was found to significantly reduce egg production in Lymnaea, leading to the proposal that dorsal body endocrine cells produce a hormone (dorsal body hormone) required for female function (Geraerts and Joose, 1975; Geraerts, 1976; Koene, 2010). In the present study, FaGlu histofluorescence was not detected in the dorsal bodies. As this finding may reflect a lower sensitivity of the FaGlu technique, the possible role of catecholaminergic signaling in the endocrine and neuronal regulation of female reproductive function in Biomphalaria merits further study in view of previous observations. In Helisoma duryi and Biomphalaria glabrata, DA was shown to stimulate secretion of perivitelline fluid from the albumen gland, a critical step for providing sufficient nutrients to stimulate secretion of perivitelline fluid from the albumen gland, a critical step for providing sufficient nutrients to the developing embryo (Saleuddin et al., 2000; Santhanagopal and Yoshino, 2000). Moreover, THli was localized to a plexus of fibers innervating the albumen gland of Helisoma and it was proposed that both central and peripheral dopaminergic neurons could participate in the regulation of vitellogenin secretion (Kiehn et al., 2001).

Catecholaminergic sensory neurons

The free swimming S. mansoni miracidium penetrates the cephalopedal body wall of B. glabrata, gaining access to the integument, where it transforms into the parasitic sporocyst form (Wright, 1973; Bayne, 2009). Chiang et al. (1974) used fluorescence microscopy to demonstrate the presence of dopaminergic fibers in the epithelium of the mouth area, tentacles, and foot of Biomphalaria. Subsequent studies resolved the somata of peripheral catecholaminergic neurons in numerous gastropod species, including Aplysia depilans (Salimova et al., 1987), Helix aspersa (Hernádi and Elekes, 1999), and Lymnaea stagnalis (Wyeth and Croll, 2011). Croll (2001, 2003) demonstrated THli-immunoreactive neurons in the siphon and gill epithelium of Aplysia, and proposed a low-threshold mechanosensory function. Faller et al. (2008) examined THli subepidermal sensory neurons in the cephalic sensory organs (CSOs: lips and tentacles) of several opisthobranchs and advanced a role for these cells in contact chemoreception or mechanoreception. Thus, while the precise sensory modality of the peripheral THli neurons of Biomphalaria remains to be determined, our findings demonstrate their presence in the cephalopedal epithelium, the major locus of miracidium penetration. THli immunoreactivity could serve as a marker for studying how infection impacts the neural innervation of the Biomphalaria integument.

Schistosoma mansoni miracidia pierce the body wall using muscular squirming and boring, aided by histolytic factors secreted by their penetration glands (Wright, 1958; Maldonado, 1967; Bayne, 2009). Depending on their modality, the epithelial THli neurons could respond to tactile or noxious stimuli produced by the penetrating miracidium or to one or more of its excretory-secretory products (ESPs; Lodes and Yoshino, 1990; Loker et al., 1992; Yoshino et al., 2001). Moreover, the relatively large (200 μm in length) miracidium is likely to rupture receptor cells, causing release of their contents in the vicinity of the parasitic larvae. Following its entrance, the parasite typically remains close to the site of penetration, establishing intimate contact with the surrounding host tissues (Pan, 1965; Wright, 1973; Yoshino et al., 2001). During its transformation to the mother sporocyst stage, additional factors and larval transformation proteins (LTPs) are released (Bayne and Yoshino, 1989; Yoshino et al., 1993; Wu et al., 2009). Complex molecular interactions occur with the host hemocyte defense systems during parasite penetration and transformation (de Jong-Brink et al., 2001; Humphries and Yoshino et al., 2003; Zahoor et al., 2009). The dopaminergic sensory neural innervation of the epithelium could be responsive to soluble signaling molecules generated by the parasite or host during this period of larval transformation (see de Jong-Brink, 2001; Yoshino et al., 2001).

Potential consequences of dopaminergic neuron activation

It is well established that the peripheral sensory neurons of gastropod species penetrate directly to the CNS (Jahan-Parwar, 1975; Bicker et al., 1982; Nakamura et al.,
Biomphalaria, the peripheral nervous system of neurons contributes to the hypothesis that DA release from peripheral sensory regulating motor systems throughout phylogeny, we hypothesize that DA release from peripheral sensory neurons could provide effective targets for parasite-induced modifications of host behavior.
